

Saliency <-> motion retinotopy bridge across the cohort (known-axis calibration)

CROSS-SUBJECT CALIBRATION -- the saliency and motion-energy bands each yield a model receptive field, hence a polar-angle map; where BOTH explain variance, do the two maps AGREE (resultant length of the paired polar differences)? This is the bridge on a KNOWN axis (retinotopy), the calibration for extending cross-encoding-space alignment to spaces we cannot read directly. Each subject shown individually (low-N/high-trial: k-of-N consistency, no MC correction).

WHAT WE EXPECT (and why): If two spatial encoding models share a visual field, R is well above its voxel-shuffle null in MOST subjects and the offset clusters near 0. A per-subject R at chance = that subject's bands do not share a spatial frame (not a group failure).

READING (candidate; the call is yours): RESULT: saliency<->motion polar agreement across 7 subjects.
